PERFORMANCE OF DOLOMITES AS HIGH FRICTION AGGREGATES

Background:

When the requirements for high friction aggregates in asphalt concrete mixtures were under development in the mid 1960s, the performance of dolomite aggregate was recognized as different from, and better than, that of limestone aggregate. The performance superiority of unblended, low residue dolomites over unblended, low residue limestones was confirmed by pavement friction tests. Since then, all dolomites have been accepted for use as high friction aggregates in the Department's standard top course mixes.

Pavement friction data from the Department's Pavement Friction Inventory Program, begun in 1980, as well as data from previously conducted research (Engineering Research Bureau, 1973-5) now shows a distinct difference in performance between pavements containing high residue dolomites and some low residue dolomites. The results of this testing are tabulated in tables 1-3.

The analysis of this data is based on the pavement polishing scheme shown in Figure 1. The concept of a "terminal polish" provides a basis for using average friction numbers to represent each site tested (Gray and Renninger, 1966; Diringier, 1990). This analysis introduces the concept that the friction level of a pavement site at terminal polish, is dependent, in large part, upon the traffic volume, expressed in terms of lane vehicle passes per day, that the pavement experiences.

Analysis of Performance Data:

Pavement friction tests were performed on 71 sites representing dolomites quarried throughout New York State. The insoluble residue content of these dolomites represent the entire range available, and were tested in both high and low traffic volume pavements, where appropriate sites were available. This analysis compares the performance of low residue dolomites, having acid insoluble residue contents of 15% or less, with that of high residue dolomites, having acid insoluble residue contents greater than 15%.

Low Residue Dolomites (A.I.R. 15% or less):

The Wappinger Dolomite is shipped into the New York City area and is, therefore, frequently used in asphalt concrete top coarse subjected to very high traffic volumes. It is the only low residue dolomite regularly used in such applications. Friction testing has shown that the Wappinger, quarried in the southern Hudson Valley and having an acid insoluble residue content in the 9-14% range (Table 1), provides adequate friction in low traffic volume applications. The same Wappinger Dolomite when used in high traffic volume pavements yields friction numbers considered inadequate by design standards (see Figure 3).

The Lockport, a dolomite quarried in central and western New York, typically has an insoluble residue content of less than 10% (Table 2). One member of the lockport Formation, the Penfield, contains from 25 to 50% insoluble residue, and will be discussed with the high residue dolomites. The data (Figure 3) shows that the Lockport Dolomite provides adequate friction in low traffic volume applications.

Dolomites from other formations were tested as well. The Beekmantown, quarried in northern St Lawrence County, typically contains between 5 and 14% insoluble residue (Table 5). These, and other similar dolomite sites, fell into a similar data distribution (Figure 3) as the Wappinger and low residue Lockport data, in low traffic volume pavements.

All these low residue dolomites share a common mineralogy and contain similar amounts of insoluble residue. With respect to pavement friction, they all perform similarly at low traffic volumes* and may, also, perform similarly at high traffic volumes*. Although pavements containing low residue Lockport, Beekmantown, and other low residue dolomites, were sought in high traffic volume applications for the Inventory Program, none were found that have Lane AADTs greater than 5,000 vehicle passes per day.

High Residue Dolomites (A.I.R. greater than 15%):

Dolomites having high insoluble residues are shown plotted in Figure 4. These include dolomites from the Penfield Member of the Lockport Formation, mentioned previously, as well as other high residue dolomites quarried in the Mohawk Valley and upper Hudson Valley. The distribution of data is similar to that of siliceous limestones, all of which have insoluble residues greater than 20% (Figure 5), and of sandstones (Figure 6). Even high traffic volume pavements (up to 10,000 lane vehicle passes per day) are performing well. The sandy nature of these high residue dolomites overcomes the polishing nature of the pure dolomite.

Summary:

All those sites containing dolomites having acid insoluble residues greater than 15% are providing adequate friction in both low and high traffic volume pavements.

Sites containing dolomites having acid insoluble residue contents less than 15% are providing adequate friction in low traffic volume pavements.

Within the population of low residue dolomite sites, the Wappinger Dolomite is failing to provide friction that meets the minimum design requirements in high traffic volume applications.

- * Low traffic volume is herein defined as 3,000 lane vehicle passes per day or less; high traffic volume is greater than 3,000 lane vehicle passes per day. The relationship between Lane AADT, expressed in lane vehicle passes per day, and AADT, as traffic volume is generally reported, is shown in the correlation chart (Figure 2).
